FINAL REPORT – 27 July 2005

EXECUTIVE SUMMARY

This report summarizes the findings and outcomes of an in-depth analysis of the 2002 and 2003 Red Hind Hydroacoustic Surveys datasets. Hydroacoustic survey datasets were originally analyzed for the presence, distribution and density of fish aggregations likely representing red hind around Puerto Rico and the surrounding islands. It is well known that numerous species utilize habitats that are considered important locations for reef fish spawning aggregations. Mobile hydroacoustic surveys provide a method to continuously sample along a transect and record the presence and position of underwater targets in three-dimensions. Therefore, the datasets were reanalyzed to isolate, count and determine the spatial location of other large targets that could represent other large reef species of interest.

Databases were produced for each year's survey. The databases include the date and time of observation and the three-dimensional position (latitude, longitude and depth) of each individual target as well as information on the target's acoustic size (proportional to fish size). Results show that solitary fish targets were in close proximity with identified aggregations as well as in areas where fish aggregations were not previously identified. In general, a greater number of fish targets were found in water column depths between 30-80 m and the majority of the fish targets were observed within 10 m of the bottom. There were, however, several targets that were off the shelf break over deep water (>>150 m). A greater number of fish were found during the surveys in 2003 in the northern regions of Puerto Rico when compared to the 2002 surveys of the southern regions. Target strength distributions suggest that several solitary targets were slightly larger as a group than the average target size of fishes in the aggregations. Findings from these analyses could be used to identify regions where fish targets are in high densities a help to prioritize regions for future sampling of large reef fish species.

Analysis of 2002 and 2003 hydroacoustic survey data for large reef fish targets around Puerto Rico

Objectives

The overall objective of this project was to reanalyze a set of databases that were originally collected during a survey for red hind (*Epinephelus guttatus*) spawning aggregations around Puerto Rico during the spring spawning season of 2002 and 2003. Original survey design is presented as a map in Figure 1. Details regarding the system specifications, transducer deployment, field calibrations, and survey design can be found elsewhere (HTI 2002, 2004). In brief, the original analysis included the delineation and identification of large aggregations of fish in the echograms followed by estimates of abundance and biomass using echo integration (HTI 2002, 2004). For this project, solitary large targets that were not associated with the previously identified aggregations were manually identified in each transect dataset. Since their identity with respect to species remains unknown, only the acoustic size and approximated fish size (based on a generalized target strength-fish length relationship) are reported.

File Processing and Data Management

The mobile survey datasets that were reanalyzed from the compliment of February 2002 and March 2003 survey databases are presented in Table 1. Individual files for each sampling day and each region or hydroacoustic system and vessel were merged into a single large database corresponding to an individual system and sampling day. The databases were converted to MS Access 2000 or 2002 for analysis and compatibility of queries for data reduction, export, tabulation and graphical analysis. The remaining files had errors from data collection (most were noted as such in the field notes) or were associated with other objectives such as *in situ* system calibration or cage trials used to calculate fish size-target strength relationships (see HTI 2002, 2004).

Each file was read into HTI Echoscape (v. 2.11 beta release b). For most files, especially 2002, the bottom was manually edited using BotEdit function according to the depth of the water column as seen on the echogram window in Echoscape. Geographic positioning systems (GPS) were an integral component of each hydroacoustic system and recorded the position of the vessel frequently. The Bottom Table in each database was processed using a Select Query in MS Access to extract the bathymetric data and convert the latitude and longitude into decimal degrees for use in the GIS. Depth and distance along transects were prepared for incorporation in the GIS to mark the path of each transect and provide depth information to compare with the depth distribution of tracked fish targets.

Manual tracking was used to accumulate groups of echoes as individual targets that would likely represent large fish that were not associated with previously identified aggregations. There were strict criteria that had to be met in order for these new targets to be identified as fish. 1) Traces included at least 3 consecutive echoes with less than a 2 ping gap between echoes (though generally 1 or less). 2) The trace pattern had a general straight line shape and direction that would indicate a single fish passing through the beam alongship as would be suggested if the transducer was moving at a rate much faster than the fish. 3) Target strengths were greater than -50dB.

Metrics were calculated for each individual fish trace. All fish that were tracked were assigned a spatial position in three dimensions. The X,Y position in latitude and longitude (decimal degrees) were provided by GPS records from the depth records as described above. The ping number that the fish entered the beam was cross-referenced to the corresponding GPS record. Z position, indicated by the range from the transducer (taken as depth from the surface), was provided by the raw echo return data. The nearest bathymetric record was then matched with the position of the fish and the distance from bottom was calculated for each fish. Finally, the average target strength (TS in dB) was calculated for each fish trace and the number of echoes for each fish trace was used to identify the original aggregations (usually much greater than 10 echoes) from the newly tracked fish (usually less than 6 echoes). The TS could be used to infer possible fish target size (total length) using established equations on regional fish species or through a generalized equation available in the literature.

Data visualization and summary of findings

Data were incorporated into a GIS to visualize the spatial data. Individual fish targets were plotted along transects according to region. In general, individual fish targets were found in mid-depth water and close to the bottom (within 5 m). Figures 2 and 3 show the spatial distribution of the fish aggregations that were identified during previous analyses (HTI 2002, 2004) and individual and solitary targets that were tracked during this project, respectively. Both figures are coded according to the year of the survey.

Comparisons between 2002 and 2003

There were more solitary fish identified from the northern coast (2003) survey than from the southern coast (2002) survey (Table 1). In 2002, the southern region held the fewest fish, whereas several fish were found in the southwest and west and in the southeast and near Vieques (Figure 3). In 2003, fish were found throughout the survey region, though more concentrated near Culebra (Figure 4). Target strengths were similar between years with a modal target strength of -42 dB and a range of -50 to -26 dB (Figure 5). Target strengths were converted to approximate fish size using the equation established by HTI (2004) and presented in Figure 6. Depth distributions for fish were similar between the two years, with most fish between 30 and 80 m deep (Figure 7a & 8a). A wider range of water column depth was sampled in 2002, and very few fish were identified in these very shallow depths. In addition, more deep water was sampled in 2002 (Figure 7b & 8b). This alone may explain why more fish were counted and identified in 2003 when compared to 2002. Finally, most fish were with 5m of the bottom in both years, though there was a wider range of distance off bottom in 2002 when compared to 2003 (Figure 7c & 8c).

Other interesting findings

Although most fish were found in close proximity to the bottom and generally within 30-80m water column depth, there were several instances where large targets were found in small groups or solitary in very deep (>>150 m) water. In most cases, it appeared from the echogram that these targets may still have been close to the shelf-break, but further detailed bathymetric data in the sampling region is necessary. These targets could represent large pelagics or large fishes associated with the shelf-break. The distribution of these targets found over deep water is presented in Figure 8 and the target strength frequency distribution is presented in Figure 10. Because most of the transect coverage were within the near-shore continental shelf, this map

represents only a small sampling of this deep-water region. Such deep targets were found in the southwest, southeast and northeast (Figure 9).

Recommendations for future data and media handling

Currently, data collected during the hydroacoustic surveys and those datasets used to produce this report are in three forms:

1. Original raw ASCII datafiles. These files are produced in real-time during field surveys using HTI Digital Echo Processor. These files have not been altered and represent all the raw echoes (*.RAW), bottom/bathymetry and GPS data (*.BOT), echo integration data (*.INT) and fish tracking parameters (*.ECH and *.FSH). Analysis of these files requires the use of HTI Echoscape or SonarData Echoview (with limitations).
2. ACCESS database files. These databases are compilations of the above datafiles as produced using HTI Echoscape. The ASCII files above in essence become Tables in a database. These ACCESS databases are saved as Version 2002, and are not compatible with versions of Microsoft Access earlier than version 2000. All information from the original raw ASCII datafiles is contained and is unaltered in these databases except for 2 cases: A) where bottom/bathymetry during data collection was set at a fixed range (usually maximum distance of ping rate), these data have been edited and updated to correspond with visual estimates of the bottom depth in the echogram, and B) fish tracks have been added as part of this contract. These tracks are identified as USER categories, different from the previously identified aggregations by HTI personnel. Further analysis of echogram representations of these databases will be require the use of HTI Echoscape, as this is the only program currently available to read these database files. Database and SQL based queries can be used to further summarize and organize these databases without the need for visualization software.
3. GIS Coverages. GIS shapefiles were created from the Bottom Table and Tracked Fish tables in each of the databases. Shapefiles were created in ArcGIS 8.3, though they can be used in any version of ArcGIS or ArcView. These files represent combinations of the Bottom and Tracked Fish tables from the Access database files. All original aggregations identified by HTI personnel (see HTI 2002, 2004) as well as fish targets that were tracked for this contract are included. Metrics included in these files include continuous bathymetric readings along transects, GPS coordinates (in decimal degrees), geocoordinates for the location of fish and aggregations each target's (or aggregation's) depth from surface, water column depth at location and distance from target to bottom, acoustic target size (in dB) and the original ASCII and database file where the fish track originated.

Raw sound data collected during both survey years are also contained on original DAT tapes with original data logs for reference. These tapes represent the acoustic data as collected in the field. Since the data collection parameters used to collect the data on the tapes is the same as was used to process the ASCII files using DEP, it is not necessary to reprocess the DAT tapes. Currently, processing these tapes would require the use of an HTI Model 241 Echosounder, a DAT player/recorder, and HTI DEP software installed on a computer controlling the

echosounder. Furthermore, while GPS data is encoded on these DAT tapes, it is not currently possible to extract the GPS information from the DAT in post-processing. Therefore, the only georeferencing information available is in the existing original raw ASCII datafiles, the Access databases and the GIS coverages. In the future, there may be advances in data handling capabilities in HTI or other third party vendor software (such as SonarData Echoview) that will permit additional analysis of the data stored on the DAT tapes, such as “samples” format and data processing. It is recommended that these tapes be maintained in a dry, cool location for storage.
